Cautions

Conclusions

- A large part of so-called second-generation SEM is the ability to model different *unobserved* groups of individuals.
- These unobserved groups can be captured through mixture models, and substantive differences across the groups can be identified.
- Mixture modeling has proved to be a useful tool for accounting for heterogeneity within a population, and the flexibility of mixture models has allowed for some innovative modeling techniques.¹

¹For detailed information about mixture modeling, see: McLachlan, G., & Peel, D. (2004). *Finite mixture models*. John Wiley & Sons.

Example

Benefits

Cautions

Conclusions

- Mixtures are particularly useful when there is unobserved heterogeneity in the data.
- In this case, the variables that cause heterogeneity in the data are not known prior to data analysis.
- The researcher hypothesizes that the population is comprised of an unknown (precise) number of substantively distinct subpopulations (or classes).
 - e.g., depression (subpopulations: non, mild, depressed); reading achievement (subpopulations: low, average, high)
- Typically, it is “known” that the population is heterogeneous, but there is no known indicator of class membership.
- Class membership must be determined based on observed data patterns.

Benefits

Cautions

Conclusions

- The Bayesian estimation framework is a complex system used to estimate models.²
- One of the key differences between frequentist (e.g., ML/EM) and Bayesian estimation is the use of *prior distributions*.

$$\textit{Posterior} = \textit{Data} * \textit{Prior} \quad (1)$$

- The prior distribution is moderated by the data and this relationship produces the *posterior distribution* (estimate).

²For more details about Bayesian estimation, see: Gelman, A., Carlin, J. B., Stern, H. S., Dunson, D. B., Vehtari, A., & Rubin, D. B. (2013). *Bayesian data analysis*. CRC press.

Benefits

Cautions

Conclusions

- Prior distributions are placed on every model parameter that we wish to estimate.
 - Think of priors similar to a “bet”.
- These distributions represent the amount of uncertainty that we have surrounding the parameters in our model.
- Specifically, priors represent our opinions about each model parameter.

Benefits

Cautions

Conclusions

- Priors allow us to incorporate our (un)certainty about model parameters using probability distributions.
 - For example, Intercept $\sim \mathcal{N}(\mu, \sigma^2)$.
 - The μ and σ^2 terms are called *hyperparameters*.
- In addition, we can also make an assumption about the particular values that the intercept can take on.
 - Diffuse: having no idea about the parameter value.
 - Informative: having a very strong idea about the parameter value.
 - Weak: Using less information than is available for the prior.
- The specification of these prior distributions is an integral part of using the Bayesian estimation framework.

- Latent class analysis (LCA) is a method used to capture different response patterns for discrete observed variables.
- With these types of variables, there can be a very large number of response patterns (e.g., 5 binary items: $2^5 = 32$ response patterns).
- LCA summarizes these response patterns into a few, substantively meaningful latent classes.

Benefits

Cautions

Conclusions

- Each individual has a probability for belonging to each class, and the individual is assigned to the class corresponding with the highest probability of membership.
- The assigned class consists of individuals with similar response patterns.
- LCA provides a succinct description of the latent classes through the different patterns of responses on the observed variables.

Inaccurate

Cautions

Conclusions

- In general, the Bayesian approach can produce a drastic improvement in accuracy in parameter estimates and mixture class proportions, especially when more informative (or weak) priors are specified.
- This approach can also help identify small but substantively real latent classes.⁶

- Informative priors perform quite well in simulation in that they are largely able to uncover small but substantively different mixture classes.⁷
- Latent class proportions are also well recovered with the use of (weakly) informative Dirichlet priors on the class proportions.⁸

Inaccurate

Cautions

Conclusions

- Mixture modeling is relatively robust to inaccuracies in prior distributions.⁹
- This is an important finding given that if the location of a prior distribution is very wrong, then the parameter value can still be accurately recovered by even moderately increasing the variance hyperparameter of the prior.
- One area not examined yet is the inaccuracy of the Dirichlet prior and the impact this would have on substantive findings.

Conclusions

- Findings have suggested that more informative priors are necessary in the context of mixture modeling.¹⁰
- Diffuse priors (e.g., $N(0, 10^{10})$) may have a more harmful impact on parameter estimates than inaccurate priors in the case of mixture modeling.

- The Bayesian estimation framework shows promise in accurately estimating mixture models under various modeling conditions.
- Recognizing that our priors will undoubtedly contain some level of inaccuracy according to the unknown population, it is important to conduct a sensitivity analysis in order to assess how much of an impact different levels of the prior have on model results.
- Openness and transparency are vital for implementing any statistical tool, but this is especially the case for Bayesian tools.

- The probability of membership in latent class c is represented by γ_c and

$$\sum_{c=1}^C \gamma_c = 1. \quad (2)$$

- For a given observed item j , the probability of response r_j given membership in class c is given by an item-response probability $\rho_{j,r_j|c}$. Note that the vector of item-response probabilities for item j conditional on latent class c always sums to 1.0 across all possible responses to item j as denoted by

$$\sum_{r_j=1}^{R_j} \rho_{j,r_j|c} = 1 \quad (3)$$

for all j observed items.

- In order to define the LCA model, the probability of a given pattern of responses must be computed. Let y_j represent the j element for the observed response pattern denoted as vector \mathbf{y} . Next, let $I(y_j = r_j)$ represents an indicator variable such that the indicator variable equals 1 when variable $j = r_j$ and 0 otherwise. Then, the probability of observing a particular set of item responses \mathbf{y} can be written as

$$P(\mathbf{Y} = \mathbf{y}) = \sum_{c=1}^C \gamma_c \prod_{j=1}^J \prod_{r_j=1}^{R_j} \rho_{j,r_j|c}^{I(y_j=r_j)}. \quad (4)$$

Specification of Latent Class Analysis

- Essentially, Equation 4 indicates that the probability of observing a particular response pattern \mathbf{y} is a function of the probability of membership in each of the C latent classes given by the γ_c term and the probability of each response conditional on latent class membership denoted by $\rho_{j,r_j|c}$. To provide an example of more concrete notation, Equation 4 can be expanded out for observed categorical items j_1, \dots, j_4 respectively:

$$P_{j=1,\dots,4} = \sum_{c=1}^C \gamma_c \rho_{j=1|c} \rho_{j=2|c} \rho_{j=3|c} \rho_{j=4|c}, \quad (5)$$

- where the probability of a given response pattern for items $j = 1, \dots, 4$ is a product of the proportion of individuals in latent class c and response probabilities for observed items $j = 1, \dots, 4$ conditioned on class membership.

- We first set up the joint probability distribution which is

$$P(\mathbf{y}, \Theta) = P(\mathbf{y}|\Theta)P(\Theta). \quad (6)$$

- Bayes theorem uses this product to compute the probability of Θ given the observed data \mathbf{y} through the following

$$P(\Theta|\mathbf{y}) = \frac{P(\mathbf{y}|\Theta)P(\Theta)}{\int_{\Theta} P(\mathbf{y}|\Theta)P(\Theta)d\Theta} \quad (7)$$

- where $P(\mathbf{y}|\Theta)$ represents the likelihood (the observed data given the distributional parameters), $P(\Theta)$ represents something called a prior distribution that is coupled with the likelihood, and $P(\Theta|\mathbf{y})$ is the posterior distribution of Θ .

- There are three specifications of the inverse Wishart that are discussed as non-informative in Asparouhov and Muthén (2010)¹²
- The first specification is $IW(0, p-1)$, which is the current default setting in *Mplus* version 7.2 for covariance matrices and mimics a uniform prior bounded at $(-\infty, \infty)$.
- The second specification is $IW(0, 0)$.
- The last specification discussed is $IW(1, p+1)$, where this prior mimics the case where off-diagonal elements (covariances) of the covariance matrix would have uniform priors bounded at $[-1, 1]$ and diagonal elements (variances or residual variances) distributed as $IG(1, 5)$.

- Although not discussed here, it is important to address some points about the inverse Wishart prior, which is commonly implemented with mixture models (for covariances).
- Changing default *Mplus* settings of this prior may create a multivariate prior that is non-positive definite.
 - When the default is changed, you have univariate inverse gamma priors on diagonals and univariate uniform or normal priors on off-diagonals.¹³
- When in doubt, seek advice from a statistician!
